1 Introduction

Our understanding of spacetime has undergone some major changes in the last hundred years. Before last century, spacetime was regarded as nothing more than a passive and static arena in which events took place. Early last century, Einstein's general relativity changed that viewpoint and promoted spacetime to an active and dynamical entity. Nowadays, many physicists also believe that spacetime, like all matter and energy, undergoes quantum fluctuations. Following John Wheeler, many of us think that space is composed of an ever-changing arrangement of bubbles called spacetime foam, a.k.a. quantum foam. To understand the terminology, let us follow Wheeler and consider the following simplified analogy which he gave in a gravity conference at the University of North Carolina in 1957. Imagine yourself flying an airplane over an ocean. At high altitude the ocean appears smooth. But as you descend, it begins to show roughness. Close enough to the ocean surface, you see bubbles and foam. Analogously, spacetime appears smooth on a large scale, but on sufficiently small scales, it will appear rough and foamy, hence the term "spacetime foam." Many physicists believe the foaminess is due to quantum fluctuations of spacetime, hence the alternative term "quantum foam." If spacetime indeed undergoes quantum fluctuations, the fluctuations will show up when we measure a distance (or a time duration), in the form of uncertainties in the measurement. Conversely, if in any distance (or time duration) measurement, we cannot measure the distance (or time duration) precisely, we interpret this intrinsic limitation to spacetime measurements as resulting from fluctuations of spacetime itself.

As we will see below, the physics of spacetime foam is intimately connected to that of black holes. It is related to the holographic principle and has bearings on the physics of clocks and computation. As far as (quantum gravity) phenomenology, the theme of this Winter School, is concerned, we can only say that it is not easy, but by no means impossible, to detect spacetime foam.[1] We encourage the students to find better ways to do so.

Before we proceed, we should mention that the approach to the physics of quantum foam adopted here is very conservative: the only ingredients we use are quantum mechanics and general relativity. Hopefully, by considering only distances (time durations) much larger than the Planck length (time) or energies (momenta) much smaller than Planck energy (momentum), a semi-classical treatment of gravity suffices and a bona fide theory of quantum gravity is not needed.

We should also make it clear at the outset that we make no assumptions on the high energy regime of the ultimate quantum gravity theory. We refrain from speculating on violations of Lorentz invariance and the consequent systematically modified dispersion relations, involving a coefficient of *fixed* magnitude and *fixed* sign, which many people believe are unavoidably induced by quantum gravity. (In the terminology of Ref. 2, these quantum gravity effects are called "systematic" effects.) The only quantum gravity effects we are concerned with in these lectures are those due to quantum fuzziness — uncertainties involving *fluctuating* magnitudes with *both* $\pm$ signs, perhaps like a fluctuation with a Gaussian distribution about zero. (In the terminology of Ref. 2, these effects are called "non-systematic" effects.)

If quantum fluctuations do make spacetime foamy on small spacetime scales, then it is natural to ask: How large are the fluctuations? How foamy is spacetime? Is there any theoretical evidence of quantum foam? And how can we detect quantum foam? In what follows, we address these questions.

The outline of this manuscript is as follows:

- *Section 2: Quantum fluctuations of spacetime.*
  By analysing a gedanken experiment for spacetime measurement, we show, in subsection 2.1, that spacetime fluctuations scale as the cube root of distances or time durations. In subsection 2.2, we show that this cube root dependence is consistent with the holographic principle. Subsection 2.3 is devoted to a comparison of this peculiar dependence on distances or time durations with the well-known random-walk problem and other quantum gravity models. In subsection 2.4, we consider the cumulative effects of individual spacetime fluctuations.
- *Section 3: Clocks, computers, and black holes.*
  We discuss how quantum foam affects the physics of clocks (subsection 3.1) and computation (subsection 3.2), and show that the physics of spacetime foam is intimately connected to that of black holes (subsection 3.3). In particular, the same underlying physics governs the computational power of black hole quantum computers. In subsection 3.4, we give the results for arbitrary spacetime dimensions.
- *Section 4: Energy-momentum uncertainties.*
  Just as there are uncertainties in spacetime measurements, there are also uncertainties in energy-momentum measurements. This topic of energy-

momentum uncertainties is given a brief treatment. Two physical implications are given: dispersion relations are modified, and (as a consequence) energy-dependent speed of light fluctuates around c.

- *Section 5: Spacetime foam phenomenology.*
  Various proposals to detect quantum foam are considered; they include: phase incoherence of light from distant galaxies (subsection 5.1), gamma ray bursts (subsection 5.2), laser-based interferometry (subsection 5.3), and ultra-high energy cosmic ray events (subsection 5.4).
- *Section 6: Summary and Conclusions.*

To make the lectures informative and more or less self-contained, "*preparatory remarks*", "*side remarks*", and "*further remarks*", too long for footnotes, are inserted when their additions are warranted. All such remarks are contained inside square brackets [ ]. They are somewhat out of the lectures' main line of development. On notations, the subscript "P" denotes Planck units. Thus $l_P \equiv (\hbar G/c^3)^{1/2} \sim 10^{-33}$ cm is the Planck length, etc.

2 Quantum Fluctuations of Spacetime

The questions are: does spacetime undergo quantum fluctuations? And if so, how large are the fluctuations? To quantify the problem, let us consider measuring a distance l. The question now is: how accurately can we measure this distance? Let us denote by δl the accuracy with which we can measure l. We will also refer to δl as the uncertainty or fluctuation of the distance l for reasons that will become obvious shortly. We will show that δl has a lower bound and will use two ways to calculate it. Neither method is rigorous, but the fact that the two very different methods yield the same result bodes well for the robustness of the conclusion. (Furthermore, the result is also consistent with well-known semi-classical black hole physics. See section 3.)

2.1 Gedanken Experiment

In the first method, we conduct a thought experiment to measure l. The importance of carrying out spacetime measurements to find the quantum fluctuations in the fabric of spacetime cannot be over-emphasized. According to general relativity, coordinates do not have any intrinsic meaning independent of observations; a coordinate system is defined only by explicitly carrying out spacetime distance measurements. Let us measure the distance between point A and point B. Following Wigner[3], we put a clock at A and a mirror at B. Then the distance l that we want to measure is given by the distance between the clock and the mirror. By sending a light signal from the clock to the mirror in a timing experiment, we can determine the distance l. However, quantum uncertainties in the positions of the clock and the mirror introduce

an inaccuracy δl in the distance measurement. We expect the clock and the mirror to contribute comparable uncertainties to the measurement. Let us concentrate on the clock and denote its mass by m. Wigner argued that if it has a linear spread δl when the light signal leaves the clock, then its position spread grows to $\delta l + \hbar l(mc\delta l)^{-1}$ when the light signal returns to the clock, with the minimum at $\delta l = (\hbar l/mc)^{1/2}$. Hence one concludes that

$$\delta l^2 \gtrsim \frac{\hbar l}{mc}. \tag{1}$$

Thus quantum mechanics alone would suggest using a massive clock to reduce the jittering of the clock and thereby the uncertainty δl. On the other hand, according to general relativity, a massive clock would distort the surrounding space severely, affecting adversely the accuracy in the measurement of the distance.

Side Remarks

[It is here that we appreciate the importance of taking into account the effects of instruments in this thought-experiment. Usually when one wants to examine a certain a field (say, an electromagnetic field) one uses instruments that are neutral (electromagnetically neutral) and massive for, in that case, the effects of the instruments are negligible. But here in our thought-experiment, the relevant field is the gravitational field. One cannot have a gravitationally neutral yet massive set of instruments because the gravitational charge is equal to the mass according to the principle of equivalence in general relativity. Luckily for us, we can now exploit this equality of the gravitational charge and the inertial mass of the clock to eliminate the dependence on m in the above inequality to promote Eq. (1) to a (low-energy) quantum gravitational uncertainty relation.]

To see this, let the clock be a light-clock consisting of a spherical cavity of diameter d, surrounded by a mirror wall of mass m, between which bounces a beam of light (along a diameter). For the uncertainty in distance measurement not to be greater than δl, the clock must tick off time fast enough that $d/c \lesssim \delta l/c$. But d, the size of the clock, must be larger than the Schwarzschild radius $r_S \equiv 2Gm/c^2$ of the mirror, for otherwise one cannot read the time registered on the clock. From these two requirements, it follows that

$$\delta l \gtrsim \frac{Gm}{c^2}. \tag{2}$$

Thus general relativity alone would suggest using a light clock (light as opposed to massive) to do the measurement.

Side Remarks

[This result can also be derived (see the first paper in Ref.[4]) in another way. If the clock has a radius $d/2$ (larger than its Schwarzschild radius r_S), then δl, the

error in the distance measurement caused by the curvature generated by the mass of the clock, may be estimated by a calculation from the Schwarzschild solution. The result is r_S multiplied by a logarithm involving $2r_S/d$ and $r_S/(l+d/2)$. For $d >> r_S$, one finds $\delta l = \frac{1}{2} r_S \log \frac{d+2l}{d}$ and hence Eq. (2) as an order of magnitude estimate.]

The product of Eq. (2) with Eq. (1) yields

$$\delta l \gtrsim (l l_P^2)^{1/3} = l_P \left(\frac{l}{l_P} \right)^{1/3}, \tag{3}$$

where $l_P = (\hbar G/c^3)^{1/2}$ is the Planck length. (Note that the result is independent of the mass of the clock and, thereby, one would hope, of the properties of the specific clock used in the measurement.) The end result is as simple as it is strange and appears to be universal: the uncertainty δl in the measurement of the distance l cannot be smaller than the cube root of $l l_P^2$.[4] Obviously the accuracy of the distance measurement is intrinsically limited by this amount of uncertainty or quantum fluctuation. We conclude that there is a limit to the accuracy with which one can measure a distance; in other words, we can never know the distance l to a better accuracy than the cube root of $l l_P^2$. Similarly one can show that we can never know a time duration τ to a better accuracy than the cube root of τt_P^2, i.e.,

$$\delta\tau \gtrsim (\tau t_P^2)^{1/3}, \tag{4}$$

where $t_P \equiv l_P/c \sim 10^{-44}$sec is the Planck time. The spacetime fluctuation translates into a metric fluctuation over a distance l and a time interval τ given by

$$\delta g_{\mu\nu} \gtrsim (l_P/l)^{2/3}, \qquad (t_P/\tau)^{2/3}, \tag{5}$$

respectively. (For a discussion of the related light-cone fluctuations, see Ref. 5.)

Because the Planck length is so inconceivably short, the uncertainty or intrinsic limitation to the accuracy in the measurement of any distance, though much larger than the Planck length, is still very small. For example, in the measurement of a distance of one kilometer, the uncertainty in the distance is to an atom as an atom is to a human being. Even for the size of the observable universe ($\sim 10^{10}$ light-years), the uncertainty is only about 10^{-13} cm.

Further Remarks

[*Fluctuations Imply Non-locality?* Fluctuations in spacetime imply that the metrics can be defined only as averages over local regions, and this gives rise to some sort of non-locality. Ahluwalia[4] has observed that spacetime measurements described above alter the spacetime metric in a fundamental manner and that this unavoidable change in the metric destroys the commutativity

(and hence locality) of position measurement operators. The gravitationally-induced nonlocality, in turn, suggests a modification of the fundamental commutators.]

Further Remarks

[*On Two Length Scales: An Analogy.* In hindsight it is not too surprising that the uncertainty δl involves two length scales, viz., the fundamental length l_P and the length l itself. There is an analogous result that is relevant for a long thin ruler which can be regarded as a one-dimensional chain of N ions with a spring between successive ions. By a straightforward quantum mechanical calculation[4], one can show that the uncertainty in the length of the ruler scales as $\sqrt{N}$ in the high-temperature limit and as $\sqrt{logN}$ in the zero temperature limit. But $N = l/a$ where l is the length of the ruler and a is the lattice constant (playing the role of l_p in the measurement of distance), so one concludes that the uncertainty of the ruler's length depends on two length scales, viz., l and a.]

Further Remarks

[*Energy Density Fluctuations Associated with Spacetime Fluctuations.* This may be a red herring, but the question has been raised[6] whether the metric fluctuations corresponding to Eq. (5) yield an unacceptably large fluctuation in energy density. To see that the associated energy density fluctuation is actually extremely (therefore acceptably) small[7], let us regard metric fluctuations as gravitational waves quantized in a box of volume V (with $\hbar = 1$ and $c = 1$):

$$\delta g(l) = l_P \sum_{\boldsymbol{k}} \frac{A(k)}{\sqrt{2Vk}} cos kl, \tag{6}$$

with the corresponding energy density fluctuations given by $\delta\rho = V^{-1} \sum A(k)^2 k$ (summation over two different polarizations is understood). In order for Eq. (6) to give Eq. (5), one needs $A(k) \sim V^{-1/2} l_P^{-1/3} k^{-11/6}$. Replacing the summation over $\boldsymbol{k}$ in $\delta\rho$, in the large volume limit, by an intgral, and using the Planck mass m_P as the upper limit, we get[7]

$$\delta\rho \sim m_P/V, \tag{7}$$

an utterly negligible energy density.]

2.2 The Holographic Principle

Alternatively we can estimate δl by applying the holographic principle.[8, 9] But for completeness, let us first recall some physics of black holes and then a heuristic derivation of the holographic principle.

Preparatory Remarks

[*Black Holes.* In our discussion of the gedanken experiment in subsection 2.1, we have already used that fact that a chargeless non-rotating black hole of mass m has a size given by

- 1. Size $r_S \sim Gm/c^2$, the Schwarzschild radius.

It is also known that a black hole behaves as if it has

- 2. Temperature $\mathcal{T} \sim \frac{\hbar c}{k_B r_S}$ where k_B is the Boltzman's constant;
- 3. Entropy $S \sim k_B \frac{r_S^2}{l_P^2}$, i.e., area in Planck units;
- 4. Finite lifetime $T_{BH} \sim \frac{G^2 m^3}{\hbar c^4}$, first found by Hawking.

Property 3 follows from properties 1 & 2 with the aid of the thermodynamic relation $dS = \frac{dE}{\mathcal{T}}$. For a black hole of one centimeter diameter, its entropy is about 10^{66} bits.

Property 4 can be derived by treating a black hole as a black body for which the emitted power (i.e., $c^2 \frac{dm}{dt}$) per unit area is given by the Stefan's law: $\frac{c^2}{area} \frac{dm}{dt} \sim \sigma \mathcal{T}^4$ where $\sigma \sim k_B^4/(\hbar^3 c^2)$ is the Stefan-Boltzmann constant. The more massive a black hole is, the longer it lasts; a solar-mass black hole is estimated to last 10^{66} years. (By comparison, the present age of the Universe is only about 13.7 billion years.) Unless mini-black holes exist, it will be impossible to directly check Hawking's result for black hole lifetime. But if the physics behind spacetime foam and black holes is the same, as will be shown in subsection 3.3, detection of spacetime foam can be taken as an indirect confirmation of Hawking's black hole evaporation process. In passing, we mention that there is increasing evidence that black holes do exist; in particular, supermassive black holes (with mass ranging from a million to a billion times the solar mass) exist at the center of many galaxies, including our own.]

Preparatory Remarks

[*Holographic Principle.* In essence, the holographic principle[10] says that although the world around us appears to have three spatial dimensions, its contents can actually be encoded on a two-dimensional surface, like a hologram. In other words, the maximum entropy of a region of space is given (aside from multiplicative factors of order 1 which we ignore as we have so far) by its surface area in Planck units. This result can be derived by appealing to black hole physics and the second law of theromodynamics as follows. Consider a system with entropy S_0 inside a spherical region Γ bounded by surface area A. Its mass must be less than that of a black hole with horizon area A (otherwise it would have collapsed into a black hole). Now imagine a spherically symmetric shell of matter collapsing onto the original system with just the right amount of energy so that together with the original mass, it forms a black hole which just fills the region Γ. The black hole so formed has entropy

$S \sim A/l_P^2$. But according to the second law of thermodynamics, $S_0 \leq S$. It follows immediately that $S_0 \lesssim A/l_P^2$, and hence the maximum entropy of a region of space is bounded by its surface area, as asserted by the holographic principle.]

With the aid of the above preparatory remarks, we are now ready to estimate δl by applying the holographic principle.[8, 9] To be more precise, let us consider a spatial region measuring l by l by l. According to the holographic principle, the number of degrees of freedom that this cubic region can contain is bounded by the surface area of the region in Planck units, i.e., l^2/l_P^2, instead of by the volume of the region as one may naively expect. This principle is strange and counterintuitive, but is supported by black hole physics in conjunction with the laws of thermodynamics (as shown above in the "Preparatory Remarks"), and it is embraced by both string theory and loop gravity, two top contenders of quantum gravity theory. So strange as it may be, let us now apply the holographic principle to deduce the accuracy with which one can measure a distance.

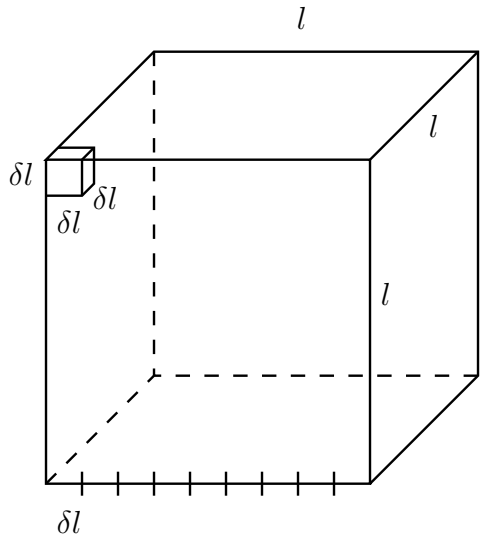

Fig. 1. Partitioning a big cube into small cubes. The big cube represents a region of space measuring l by l by l. The small cubes represent the smallest physically-allowed cubes measuring δl by δl by δl that can be lined up to measure the length of each side of the big cube. Strangely, the size of the small cubes is *not* universal, but depends on the size of the big cube. A simple argument based on this construction leads to the holographic principle.

First, imagine partitioning the big cube into small cubes [see Fig. 1]. The small cubes so constructed should be as small as physical laws allow so that

intuitively we can associate one degree of freedom with each small cube. In other words, the number of degrees of freedom that the region can hold is given by the number of small cubes that can be put inside that region. But how small can such cubes be? A moment's thought tells us that each side of a small cube cannot be smaller than the accuracy δl with which we can measure each side l of the big cube. This can be easily shown by applying the method of contradiction: assume that we can construct small cubes each of which has sides less than δl. Then by lining up a row of such small cubes along a side of the big cube from end to end, and by counting the number of such small cubes, we would be able to measure that side (of length l) of the big cube to a better accuracy than δl. But, by definition, δl is the best accuracy with which we can measure l. The ensuing contradiction is evaded by the realization that each of the smallest cubes (that can be put inside the big cube) indeed measures δl by δl by δl. Thus, the number of degrees of freedom in the region (measuring l by l by l) is given by $l^3/\delta l^3$, which, according to the holographic principle, is no more than l^2/l_p^2. It follows that δl is bounded (from below) by the cube root of ll_P^2, the same result as found above in the gedanken experiment argument. Thus, to the extent that the holographic principle is correct, spacetime indeed fluctuates, forming foams of size δl on the scale of l. Actually, considering the fundamental nature of spacetime and the ubiquity of quantum fluctuations, we should reverse the argument and then we will come to the conclusion that the "strange" *holographic principle has its origin in quantum fluctuations of spacetime.*[1]

Side Remarks

[It is quite possible that the effective dimensional reduction of the the number of degrees of freedom (embodied in the holographic principle) *may* have a dramatic effect on the ultraviolet behaviour of a quantum field theory.]

2.3 Quantum Gravity Models

The consistency of the uncertainties in distance measurements with the holographic principle is reassuring. But the dependence of the fluctuations in distance on the cube root of the distance is still perplexing. To gain further insight into this strange state of affairs, let us compare this peculiar dependence on distance with the well-known one-dimensional random-walk problem. For a random walk of steps of equal size, with each step equally likely to either direction, the root-mean-square deviation from the mean is given by the size of each step multiplied by the square root of the number of steps. It is now simple to concoct a random-walk model[12, 13] for the fluctuations of distances in quantum gravity. Consider a distance l, which we partition into l/l_P units

[1] Recently, Scardigli and Casadio[11] claim that the expected holographic scaling seems to hold only in (3+1) dimensions and only for the "generalized uncertainty principle" found above for δl.

each of length l_P. In the random-walk model of quantum gravity, l_P plays the role of the size of each step and l/l_P plays the role of the number of steps. The fluctuation in distance l is given by l_P times the square root of l/l_P, which comes out to the square root of ll_P. This is much bigger than the cube root of ll_P^2, the fluctuation in distance measurements found above.

The following interpretation of the dependence of δl on the cube root of l now presents itself. As in the random-walk model, the amount of fluctuations in the distance l can be thought of as an accumulation of the l/l_P individual fluctuations each by an amount plus or minus l_P. But, for this case, the individual fluctuations cannot be completely random (as opposed to the random-walk model); actually successive fluctuations must be *entangled* and somewhat *anti-correlated* (i.e., a plus fluctuation is slightly more likely followed by a minus fluctuation and vice versa), in order that together they produce a total fluctuation less than that in the random-walk model. This small amount of anti-correlation between successive fluctuations (corresponding to what statisticians call fractional Brownian motion with self-similarity parameter $\frac{1}{3}$) must be due to quantum gravity effects. Since the cube root dependence on distance has been shown to be consistent with the holographic principle, we will, for the rest of this subsection, refer to this case that we have found (marked by an arrow in Fig. 2) as the holography model.

Side Remarks

[We leave it as an exercise (albeit a rather non-trivial one) to the students to seek a more microscopic understanding of the holographic principle, at the level of random walk for the random-walk model.]

On the other hand, if successive fluctuations are completely anti-correlated, i.e., a fluctuation by plus l_P is followed by a fluctuation by minus l_P which is succeeded by plus l_P etc. in the pattern $+-+-+-+-+-...$, then the fluctuation of a distance l is given by the minuscule l_P,[14] independent of the size of the distance. Thus the holography model falls between the two extreme cases of complete randomness (square root of ll_P) and complete anti-correlation (l_P). For completeness, we mention that *a priori* there are also models with correlating successive fluctuations. But these models yield unacceptably large fluctuations in distance and time duration measurements — we will see below that these models (corresponding to the hatched line to the right of the random-walk model shown in Fig. 2) have already been observationally ruled out.

2.4 Cumulative Effects of Spacetime Fluctuations

Let us now examine the cumulative effects[15] of spacetime fluctuations over a large distance. Consider a distance l, and divide it into l/λ equal parts each of which has length λ. If we start with $\delta\lambda$ from each part, the question is how

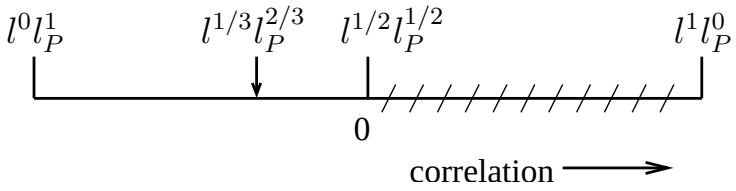

Fig. 2. Lower bounds on δl for the various quantum gravity models. The fluctuation of the distance l is given by the sum of l/l_P fluctuations each by plus or minus l_P. Spacetime foam appears to choose a small anti-correlation (i.e., negative correlation) between successive fluctuations, giving a cube root dependence in the number l/l_p of fluctuations for the total fluctuation of l (indicated by the arrow). It falls between the two extreme cases of complete randomness, i.e., zero (anti-)correlation (corresponding to $\delta l \sim l^{1/2} l_P^{1/2}$) and complete anti-correlation (corresponding to $\delta l \sim l_P$). Quantum gravity models corresponding to positive correlations between successive fluctuations (indicated by the hatched portion) are observationally ruled out. See "Further Remarks" in subsection 5.1.

do the l/λ parts add up to δl for the whole distance l. In other words, we want to find the cumulative factor $\mathcal{C}$ defined by

$$\delta l = \mathcal{C}\, \delta\lambda, \tag{8}$$

For the holography model, since $\delta l \sim l^{1/3} l_P^{2/3} = l_P (l/l_P)^{1/3}$ and $\delta\lambda \sim \lambda^{1/3} l_P^{2/3} = l_P (\lambda/l_P)^{1/3}$, the result is

$$\mathcal{C} = \left(\frac{l}{\lambda}\right)^{1/3}. \tag{9}$$

For the random-walk model, the cumulative factor is given by $\mathcal{C} = (l/\lambda)^{1/2}$; for the model corresponding to complete anti-correlation, the cumulative factor is $\mathcal{C} = 1$, *independent* of l. Let us note that, for all quantum gravity models (except for the physically disallowed model corresponding to complete correlation between successive fluctuations), the cumulative factor is *not* linear in (l/λ), i.e., $\frac{\delta l}{\delta\lambda} \neq \frac{l}{\lambda}$. (In general, it is much smaller than l/λ). The reason for this is obvious: the $\delta\lambda$'s from the l/λ parts in l do *not* add coherently. It makes no sense, e.g., to say, for the completely anti-correlating model, that $\delta l \sim \delta\lambda \times l/\lambda \gtrsim l_P l/\lambda$ because it is inconsistent to use the completely anti-correlating model for $\delta\lambda$ while using the completely correlating model for the cumulative factor.

Note that the above discussion on cumulative effects is valid for *any* λ between l and l_P, i.e., it does not matter how one partitions the distance l. In particular, for our holography model, one can choose to partition l into units of Planck length l_P, the smallest physically meaningful length. Then (for $\lambda = l_P$) using $\delta l_P \sim l_P^{1/3} \times l_P^{2/3} = l_P$, one recovers $\delta l \sim (l/l_P)^{1/3} \times l_P = l^{1/3} l_P^{2/3}$, with the dependence on the cube root of l being due to a small amount of

anti-correlation between successive fluctuations as noted above. The fact that we can choose λ as small as the Planck length in the partition indicates that, in spite of our earlier disclaimer, it may even be meaningful to consider, in the semi-classical framework we are pursuing, fluctuations of distances close to the Planck length.

Now that we know where the holography model stands among the quantum gravity models, we will restrict ourselves to discuss this model only for the rest of the lectures.

3 Clocks, Computers, and Black Holes

So far there is no experimental evidence for spacetime foam, and, as we will show shortly, no direct evidence is expected in the very near future. In view of this lack of experimental evidence, we should at least look for theoretical corroborations (aside from the "derivation" of the holographic principle discussed in subsection 2.2). Fortunately such corroborations do exist — in the sector of black hole physics (this should not come as a surprise to the experts). To show that, we have to make a small detour to consider clocks and computers[16, 17] first.

3.1 Clocks

Consider a clock (technically, a simple and "elementary" clock, not composed of smaller clocks that can be used to read time separately or sequentially), capable of resolving time to an accuracy of t, for a period of T (the running time or lifetime of the clock). Then bounds on the resolution time and the lifetime of the clock can be derived by following an argument very similar to that used above in the analysis of the gedanken experiment to measure distances. Actually, the two arguments are so similar that one can identify the corresponding quantities. [See Table.]

The corresponding quantities in the discussion of distance measurements (first column), time duration measurements (second column), clocks (third column), and computers (fourth column) appear in the same row in the following Table.

distance measurements	time duration measurements	clocks	computers
$\delta l/c$	$\delta\tau$	t	$1/\nu$
l/c	τ	T	I/ν
$\delta l^2 \gtrsim \hbar l/mc$	$\delta\tau^2 \gtrsim \hbar\tau/mc^2$	$t^2 \gtrsim \hbar T/mc^2$	$I\nu \lesssim mc^2/\hbar$
$\delta l \gtrsim Gm/c^2$	$\delta\tau \gtrsim Gm/c^3$	$t \gtrsim Gm/c^3$	$\nu \lesssim c^3/Gm$
$l/(\delta l)^3 \lesssim l_P^{-2}$ $(\delta l \gtrsim l^{1/3} l_P^{2/3})$	$\tau/(\delta\tau)^3 \lesssim t_P^{-2}$	$T/t^3 \lesssim t_P^{-2}$	$I\nu^2 \lesssim t_P^{-2} = c^5/\hbar G$

For the discussion of clocks, one argues that at the end of the running time T, the linear spread of the clock (of mass m) grows to $\delta l \gtrsim (\hbar T/m)^{1/2}$. But the position uncertainty due to the act of time measurement must be smaller than the minimum wavelength of the quanta used to read the clock: $\delta l \lesssim ct$, for the entire period T. It follows that[3, 16]

$$t^2 \gtrsim \frac{\hbar T}{mc^2}, \tag{10}$$

which is the analogue of Eq. (1). On the other hand, for the clock to be able to resolve time interval as small as t, the cavity of the light-clock must be small enough such that $d \lesssim ct$; but the clock must also be larger than the Schwarzschild radius $2Gm/c^2$ so that the time registered by the clock can be read off at all. These two requirements are satisfied with

$$t \gtrsim \frac{Gm}{c^3}, \tag{11}$$

the analogue of Eq. (2). One can combine the above two equations to give[16]

$$T/t^3 \lesssim t_P^{-2} = \frac{c^5}{\hbar G}, \tag{12}$$

which relates clock precision to its lifetime. Numerically, for example, for a femtosecond (10^{-15} sec) precision, the bound on the lifetime of a simple clock is 10^{34} years.

3.2 Computers

Preparatory Remarks

[*Energies Determine the Rate of Computation.* During a logical operation, the bits in a computer go from one state to another. One can use the Heisenberg uncertainty principle in the form $\Delta E \Delta t \geq \hbar$ to show that a quantum state with spread in energy ΔE takes time at least $\Delta t = \pi\hbar/2\Delta E$ to evolve to an orthogonal state. One can further show[18, 19] that it takes a system with average energy E at least the amount of time $\Delta t = \pi\hbar/2E$ to do so. Thus the speed of computation for a computer with total energy E distributed among its various logic gates (labelled by l) is bounded by

$$\sum_l \frac{1}{\Delta t_l} \leq \sum_l \frac{2E_l}{\pi\hbar} = \frac{2E}{\pi\hbar} \sim \frac{E}{\hbar}. \tag{13}$$

That is, energy limits the speed of computation. We will see that a black hole computer can saturate this bound.]

One can easily translate the relations for clocks given in the above subsection into useful relations for a simple computer (technically, it refers to

a computer designed to perform highly serial computations, i.e., one that is not divided into subsystems computing in parallel). Since the resolution time t for clocks is the smallest time interval relevant in the problem, the fastest possible processing frequency is given by its reciprocal, i.e., $1/t$. Thus if ν denotes the clock rate of the computer, i.e., the number of operations per bit per unit time, then it is natural to identify ν with $1/t$. To identify the number I of bits of information in the memory space of a simple computer, we recall that the running time T is the longest time interval relevant in the problem. Thus, the maximum number of steps of information processing is given by the running time divided by the resolution time, i.e., T/t. It follows that one can identify the number I of bits of the computer with T/t.[2] In other words, the translations from the case of clocks to the case of computers consist of substituting the clock rate of computation for the reciprocal of the resolution time, and substituting the number of bits for the running time divided by the resolution time. [See Table.] The bounds on the precision and lifetime of a clock given by Eqs. (10), (11) and (12) are now translated into a bound on the rate of computation and number of bits in the computer, yielding respectively

$$I\nu \lesssim \frac{mc^2}{\hbar}, \qquad \nu \lesssim \frac{c^3}{Gm}, \qquad I\nu^2 \lesssim \frac{c^5}{\hbar G} \sim 10^{86}/sec^2. \tag{14}$$

The first inequality shows that the speed of computation is bounded by the energy of the computer divided by Planck's constant, in agreement with the result given by Eq. (13), found by Margolus and Levitin[18], and by Lloyd[19] (for the ultimate limits to computation). The last bound is perhaps even more intriguing: it requires the product of the number of bits and the square of the computation rate for *any* simple computer to be less than the square of the reciprocal of Planck time,[16] which depends on relativistic quantum gravity (involving c, $\hbar$, and G). This relation links together our concepts of information/computation, relativity, gravity, and quantum uncertainty. The link between information and spacetime foam is perhaps not surprising because, as the above discussion of the holographic principle shows, the maximum amount of information that can be put into a region of space depends on how small the bits are, and they cannot be smaller than the foams of spacetime. So the ultimate power of computation also depends on the structure of spacetime foam. Numerically, the computation bound given by Eq. (14) is about seventy-six orders of magnitude above what is available for a current lap-top computer performing ten billion operations per second on ten billion bits, for which $I\nu^2 \sim 10^{10}/sec^2$.

[2] One can think of a tape of length cT as the memory space, partitioned into bits each of length ct.

3.3 Black Holes

Black Hole Lifetime

Now we can apply what we have learned about clocks and computers to black holes.[16, 17] Let us consider using a black hole to measure time. It is reasonable to use the light travel time around the black hole's horizon as the resolution time of the clock, i.e., $t \sim \frac{Gm}{c^3} \equiv t_{BH}$, then from Eq. (10), one immediately finds that

$$T \sim \frac{G^2 m^3}{\hbar c^4} \equiv T_{BH}. \tag{15}$$

We have just recovered Hawking's result for black hole lifetime!

Black Hole Computers

Finally, let us consider using a black hole to do computations. This may sound like a ridiculous proposition. But if we believe that black holes evolve according to quantum mechanical laws, it is possible, at least in principle, to program black holes to perform computations[19] that can be read out of the fluctuations in the Hawking black hole radiation. How large is the memory space of a black hole computer, and how fast can it compute? Applying the results for computation derived above, we readily find the number of bits in the memory space of a black hole computer, given by the lifetime of the black hole divided by its resolution time as a clock, to be

$$I = \frac{T_{BH}}{t_{BH}} \sim \frac{m^2}{m_P^2} \sim \frac{r_S^2}{l_P^2}, \tag{16}$$

where $m_P = \hbar/(t_P c^2)$ is the Planck mass, m and r_S^2 denote the mass and event horizon area of the black hole respectively. This gives the number of bits I as the event horizon area in Planck units, in agreement with the identification of black hole entropy. (Recall that entropy S and the number of bits I are related by $S = k_B I ln 2$.)

Side Remarks

[Recall that the only property of a black hole we have used in the analysis of the gedanken experiment to measure distances (subsection 2.1) and in the analysis of clocks (subsection 3.1) is that it has a size given by the Schwarzschild radius $r_S \sim Gm/c^2$ (property 1 in first set of "Preparatory Remarks" in subsection 2.2). Now we have recovered the results for black hole entropy (property 3) and lifetime (property 4). Actually one can also recover the result for black hole temperature $\mathcal{T} \sim \hbar c/k_B r_S$ (property 2) by using the thermodynamic relation $\mathcal{T} = dE/dS$.]

Furthermore, the number of operations per unit time for a black hole computer is given by

$$I\nu = \frac{T_{BH}}{t_{BH}} \times \frac{1}{t_{BH}} \sim \frac{mc^2}{\hbar}, \tag{17}$$

its energy divided by Planck's constant, in agreement with the result found by Lloyd[19]. It is curious that all the bounds on computation discussed above are saturated by black hole computers. Thus one can even say that once they are programmed to do computations, black holes are the ultimate simple computers.

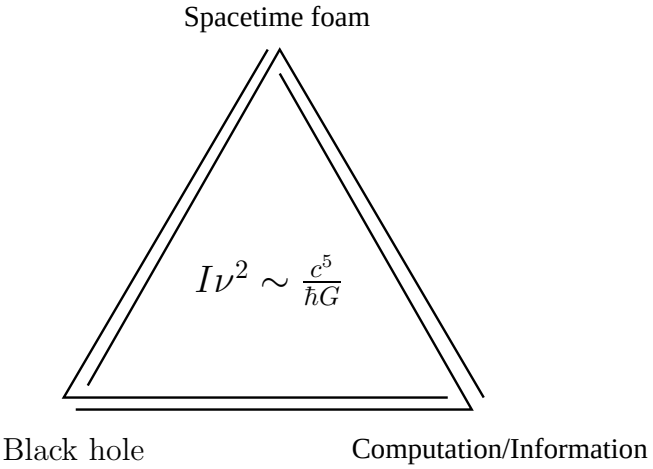

Fig. 3. The quantum foam-black hole-computation/information triangle. At the center of the triangle is the *universal* relation: $I\nu^2 \sim c^5/\hbar G$, where I is the number of bits in the memory space, and ν is the clock rate of computation of a black hole computer. This relation is a combined product of the physics behind spacetime foam, black holes, and computation/information.

All these results reinforce the conceptual interconnections of the physics underlying spacetime foam, black holes, and computation. It is intersting that these three subjects share such intimate bonds and are brought together here [see Fig. 3]. The internal consistency of the physics we have uncovered also vindicates the simple (some would say overly simple) arguments we present in section 2 in the derivation of the limits to spacetime measurements. It is as if Nature approves simplicity, and tries to get away with as much simplicity as possible. Perhaps it actually follows Albert Einstein's dictum: Everything should be made as simple as possible, but not simpler.

Side Remarks

[It was John Wheeler who coined the terms "spacetime foam" and "black holes". Also famous for his phrase "its from bits", he was among the first physicists to recognize the importance of quantum information and quantum computation. To honor him for the promotion of these ideas, we should perhaps call the triangle in Fig. 3 the Wheeler Triangle.]

3.4 Results for Arbitrary Dimensions

So far we have been doing $(3+1)$-dimensional physics, but it is theoretically interesting to generalize the discussion to arbitrary $(n+1)$ dimensions. In this subsection we set $c = 1$ and $\hbar = 1$ for convenience. In $(n+1)$ dimensions, Newton's constant G has the dimension of $[length]^{n-1}$. The corresponding Schwarzschild radius is given by[20] $r_S \sim (mG)^{\frac{1}{n-2}}$. One can carry out a gedankan experiment to measure a distance as described in subsection 2.1. Again quantum mechanics imposes the bound $\delta l^2 \gtrsim l/m$; but gravity demands $\delta l^{n-2} \gtrsim mG$. It follows that the uncertainty in distance measurements is given by

$$\delta l \gtrsim (Gl)^{\frac{1}{n}}. \tag{18}$$

Next, following the argument given in subsection 2.2, one can alternatively use the holographic principle (that the number of degrees of freedom in an n-dimensional hyper-cube is bounded by l^{n-1}/G) and the fact that the number of small hyper-cubes inside the big hyper-cube is given by $(l/\delta l)^n$, to derive Eq. (18).[3]

The discussion given in subsection 3.3 for black holes can be duplicated for the case of arbitrary $(n+1)$ dimensions. For a black hole used as a clock, we get

$$t_{BH} \sim (mG)^{\frac{1}{n-2}}, \qquad T_{BH} \sim (m^n G^2)^{\frac{1}{n-2}}, \tag{19}$$

for its resolution time and its total running time respectively. Correspondingly, the number of bits a black hole computer can hold in its memory space and the bound on its rate of computation are respectively given by

$$I_{BH} \sim \frac{r_S^{n-1}}{G}; \qquad I\nu \sim m. \tag{20}$$

For the rest of the lectures, we go back to $3+1$ dimensions.

[3] Note the somewhat different conclusions (for $n \neq 3$) reached in Ref.[11] where a different bound from gravity (by following an argument similar to that given in "Side Remarks" after Eq. (2)) is used.

4 Energy-Momentum Uncertainties

Just as there are uncertainties in spacetime measurements, there are also uncertainties in energy-momentum measurements due to spacetime foam effects. Thus there is a limit to how accurately we can measure and know the energy and momentum of a system.[4] Imagine sending a particle of momentum p to probe a certain structure of spatial extent l so that $p \sim \hbar/l$. It follows that $\delta p \sim (\hbar/l^2)\delta l$. Spacetime fluctuations $\delta l \gtrsim l(l_P/l)^{2/3}$ can now be used to give

$$\delta p = \beta p \left(\frac{p}{m_P c}\right)^{2/3}, \tag{21}$$

where *a priori* $\beta \sim 1$. The corresponding statement for energy uncertainties is

$$\delta E = \gamma E \left(\frac{E}{E_P}\right)^{2/3}, \tag{22}$$

where $E_P = m_P c^2 \sim 10^{19}$ GeV is the Planck energy and *a priori* $\gamma \sim 1$. We emphasize that all the uncertainties take on $\pm$ sign with equal probability (most likely, a Gaussian distribution about zero). Thus at energy-momentum far below the Planck scale, the energy-momentum uncertainties are very small, suppressed by a fractional (two-thirds) power of the Planck energy-momentum. (For example, the uncertainty in the energy of a particle of ten trillion electron-volts is about a thousand electron-volts.)

Modified Dispersion Relations

Energy-momentum uncertainties affect both the energy-momentum conservation laws and dispersion relations. Energy-momentum is conserved up to energy-momentum uncertainties due to quantum foam effects, i.e., $\Sigma(p_i^\mu + \delta p_i^\mu)$ is conserved, with p_i^μ being the average values of the various energy-momenta. On the other hand the dispersion relation is now generalized to read

$$E^2 - p^2c^2 - \epsilon p^2 c^2 \left(\frac{pc}{E_P}\right)^{2/3} = m^2 c^4, \tag{23}$$

for high energies with $E \gg mc^2$. *A priori* we expect $\epsilon \sim 1$ and is independent of β and γ. But due to our present ignorance of quantum gravity, we are not in a position to make any definite statements. In fact, it is possible that $\epsilon = 2(\beta - \gamma)$, which would be the case if the modified dispersion relation is given by $(E + \delta E)^2 - (p + \delta p)^2 c^2 = m^2 c^4$, with δp and δE given by Eqs. (21) and (22) respectively.

A Fluctuating Speed of Light

The modified dispersion relation discussed above has an interesting consequence for the speed of light.[21, 22] Applying Eq. (23) to the massless photon yields

$$E^2 \simeq c^2 p^2 + \epsilon E^2 \left(\frac{E}{E_P}\right)^{2/3}. \tag{24}$$

The speed of (massless) photon

$$v = \frac{\partial E}{\partial p} \simeq c\left(1 + \frac{5}{6}\epsilon \frac{E^{2/3}}{E_P^{2/3}}\right), \tag{25}$$

becomes energy-dependent and fluctuates around c. For example, a photon of ten trillion electron-volt energy has a speed fluctuating about c by one centimeter per second.

5 Spacetime Foam Phenomenology

Because the Planck length $l_P \sim 10^{-33}$ cm is so minuscule, the Planck time $t_P \sim 10^{-44}$ sec so short, and the Planck energy $E_P \sim 10^{28}$ eV so high, spacetime foam effects, suppressed by Planck scales, are exceedingly small. Accordingly, they are very hard to detect. The trick will be to find ways to amplify the small effects.[1]

5.1 Phase Incoherence of Light from Extra-galactic Sources

One way to amplify the minute effects is to add up many such effects, like collecting many small raindrops to fill a reservoir. Consider light coming to us from extragalactic sources. Over one wavelength, the phase of the light-waves advances by 2π; but due to spacetime foam effects, this phase fluctuates by a small amount. The idea is that the fluctuation of the phase over one wavelength is extremely small, but light from distant galaxies has to travel a distance of many wavelengths. It is possible that over so many wavelengths, the fluctuations can cumulatively add up to a detectable level at which point the phase coherence for the light-waves is lost. Loss of phase coherence would mean the loss of interference patterns. Thus the strategy is to look for the blurring of images of distant galaxies in powerful telescopes like the Hubble Space Telescope. This technique to detect spacetime foam was proposed by Lieu and Hillman[23], and elaborated by Ragazzoni and his collaborators[24].

The proposal deals with the phase behavior of radiation with wavelength λ received from a celestial source located at a distance l away. Fundamentally, the wavelength defines the minimum length scale over which physical quantities such as phase and group velocities (and hence dispersion relations) can be defined. Thus, the uncertainty in λ introduced by spacetime foam is the starting point for this analysis. A wave will travel a distance equal to its own wavelength λ in a time $t = \lambda/v_g$ where v_g is the group velocity of propagation, and the phase of the wave consequently changes by an amount

$$\phi = 2\pi \frac{v_p t}{\lambda} = 2\pi \frac{v_p}{v_g}, \tag{26}$$

(i.e., if $v_p = v_g, \phi = 2\pi$) where v_p is the phase velocity of the light wave. Quantum gravity fluctuations, however, introduce random uncertainties into this phase which is simply

$$\delta\phi = 2\pi\, \delta\!\left(\frac{v_p}{v_g}\right). \tag{27}$$

Due to quantum fluctuations of energy-momentum[4] and the modified dispersion relations, we obtain

$$\delta\!\left(\frac{v_p}{v_g}\right) \sim \pm \left(\frac{E}{E_P}\right)^{2/3} = \pm \left(\frac{l_P}{\lambda}\right)^{2/3}, \tag{28}$$

where we have used $v_p = E/p$ and $v_g = dE/dp$, and $E/E_P = l_P/\lambda$. We emphasize that this may be either an incremental advance or a retardation in the phase.

In travelling over the macroscopically large distance, l, from source to observer an electromagnetic wave is continually subjected to random, incoherent spacetime fluctuations. Therefore, by our previous argument given in subsection 2.4, the cumulative statistical phase dispersion is $\Delta\phi = \mathcal{C}\delta\phi$ with the cumulative factor $\mathcal{C} = (l/\lambda)^{1/3}$, that is

$$\Delta\phi = 2\pi a \left(\frac{l_P}{\lambda}\right)^{2/3} \left(\frac{l}{\lambda}\right)^{1/3} = 2\pi a \frac{l_P^{2/3} l^{1/3}}{\lambda}, \tag{29}$$

where $a \sim 1$. (This is our fundamental disagreement[15] with Lieu and Hillman who assume that the microscale fluctuations induced by quantum foam into the phase of electromagnetic waves are coherently magnified by the factor l/λ rather than $(l/\lambda)^{1/3}$.) Thus even the active galaxy PKS1413+135, an example used by Lieu and Hillman, for which $\lambda \simeq 1.6\mu m$ and $l \simeq 1.216$ Gpc, is not far enough to make the light wave front noticeably distorted. A simple calculation[15] shows that, over four billion light years, the phase of the light waves fluctuates only by $\Delta\phi \sim 10^{-9} \times 2\pi$, i.e., only by one billionth of what is required to lose the sharp ring-like interference pattern around the galaxy which, not surprisingly, is observed[25] by the Hubble Telescope. This example illustrates the degree of difficulty which one has to overcome to detect spacetime foam. The origin of the difficulty can be traced to the incoherent nature of the spacetime fluctuations (i.e., the anticorrelations between successive fluctuations).

Further Remarks

[*Ruling Out the Random-Walk Model of Quantum Gravity.* But not all is lost with Lieu and Hillman's proposal. One can check that the proposal can

be used to rule out[15], if only marginally, the random-walk model of quantum gravity, which would (incorrectly) predict $\Delta\phi \sim 2\pi(l_P/\lambda)^{1/2}(l/\lambda)^{1/2} = 2\pi(l_P l)^{1/2}/\lambda \sim 10 \times 2\pi$, a large enough phase fluctuation for light from PKS1413+135 to lose phase coherence, contradicting evidence of diffraction patterns from the Hubble Telescope observation. It follows that models corresponding to correlating successive fluctuations are also ruled out.]

5.2 High Energy γ Rays from Distant GRB

For another idea to detect spacetime foam, let us recall Eq. (25) that, due to quantum fluctuations of spacetime, the speed of light fluctuates around c and the fluctuations increase with energy. Thus for photons (quanta of light) emitted simultaneously from a distant source coming towards our detector, we expect an energy-dependent spread in their arrival times. To maximize the spread in arrival times, we should look for energetic photons from distant sources. High energy gamma rays from distant gamma ray bursts[21] fit the bill. So the idea is to look for a noticeable spread in arrival times for such high energy gamma rays from distant gamma ray bursts. This proposal was first made by G. Amelino-Camelia et al.[21] in another context.

To underscore the importance of using the correct cumulative factor to estimate the spacetime foam effect, let us first proceed in a naive manner. At first sight, the fluctuating speed of light $\delta v \sim c(E/E_P)^{2/3}$ (see Eq. (25)) would *seem* to yield[22] an energy-dependent spread in the arrival times of photons of the *same* energy E given by $\delta t \sim \delta v(l/c^2) \sim t(E/E_P)^{2/3}$, where $t = l/c$ is the average overall time of travel from the photon source (distance l away). Furthermore, the modified energy-momentum dispersion relation would seem to predict time-of-flight differences between simultaneously-emitted photons of different energies, E_1 and E_2, given by $\delta t \simeq t(E_1^{2/3} - E_2^{2/3})/E_P^{2/3}$. But these results for the spread of arrival times of photons are *not* correct, because we have inadvertently used $l/\lambda \sim Et/\hbar$ as the cumulative factor instead of the correct factor $(l/\lambda)^{1/3} \sim (Et/\hbar)^{1/3}$. Using the correct cumulative factor, we get a much smaller $\delta t \sim t^{1/3}t_P^{2/3}$ for the spread in arrival time of the photons of the same energy. Thus the result is that the time-of-flight differences increase only with the cube root of the average overall time of travel from the gamma ray bursts to our detector, leading to a time spread too small to be detectable.[1]

5.3 Interferometry Techniques

Suppressed by the extraordinarily short Planck length, fluctuations in distances, even large distances, are very small. So, to measure such fluctuations, what one needs is an instrument capable of accurately measuring fluctuations in length over long distances. Modern gravitational-wave interferometers, having attained extraordinary sensitivity, come to mind. The idea of using gravitational-wave interferometers to measure the foaminess of spacetime

was proposed by Amelino-Camelia[12] and elaborated by the author and van Dam[8]. Modern gravitational-wave interferometers are sensitive to changes in distances to an accuracy better than 10^{-18} meter. To attain such sensitivity, interferometer researchers have to contend with many different noises, the enemies of gravitational-wave research, such as thermal noise, seismic noise, and photon shot noise. To this list of noises that infest an interferometer, we now have to add the faint yet ubiquitous noise from spacetime foam. In other words, even after one has subtracted all the well-known noises, there is still the noise from spacetime fluctuations left in the read-out of the interferometer.

The secret of this proposal to detect spacetime foam lies in the existence of another length scale[12] available in this particular technique, in addition to the minuscule Planck length. It is the scale provided by the frequency f of the interferometer bandwidth. What is important is whether the length scale $l_P^{2/3}(c/f)^{1/3}$, characteristic of the noise from spacetime foam at that frequency, is comparable to the sensitivity level of the interferometer. The hope is that, within a certain range of frequencies, the experimental limits will soon be comparable to the theoretical predictions for the noise from quantum foam.

The detection of spacetime foam with interferometry techniques is also helped by the fact that the correlation length of the noise from spacetime fluctuations is extremely short, as the characteristic scale is the Planck length. Thus, this faint noise can be easily distinguished from the other sources of noise because of this lack of correlation. In this regard, it will be very useful for the detection of spacetime foam to have two nearby interferometers.

To proceed with the analysis, we recall that the displacement noise due to spacetime foam that involves a time interval t is given by $\delta l(t) \sim l_P^{2/3}(ct)^{1/3}$. Next we decompose the displacement noise in terms of the associated displacement amplitude spectral density[26] $S(f)$ of frequency f. For a frequency-band limited from below by the time of observation t, $\delta l(t)$ and $S(f)$ are related by

$$(\delta l(t))^2 = \int_{1/t} [S(f)]^2 df. \tag{30}$$

For the displacement noise due to quantum foam, one can easily check that the amplitude spectral density is given by $S(f) \sim c^{1/3} l_P^{2/3} f^{-5/6}$, inversely proportional to (the 5/6th power of) frequency. So one can optimize the performance of an interferometer at low frequencies. As lower frequency detection is possible only in space, interferometers like the proposed Laser Interferometer Space Antenna[27] may enjoy a certain advantage.

To be specific, let us now compare the predicted spectal density from quantum foam noise with the noise level projected for the Laser Interferometer Gravitational-Wave Observatory. The "advanced phase" of LIGO[28] is expected to achieve a displacement noise level of less than $10^{-20}\mathrm{mHz}^{-1/2}$ near 100 Hz; one can show that this would translate into a probe of l_P down to 10^{-31} cm, a mere hundred times the physical Planck length. But can we then conclude that LIGO will be within striking distance of detecting quantum

foam? Alas, the above optimistic estimate is based on the assumption that spacetime foam affects the paths of all the photons in the laser beam coherently. But, in reality, this can hardly be the case. Since the total effect on the interferometer is based on averaging over all photons in the wave front, the incoherent contributions from the different photons are expected to cut down the sensitivity of the interferometer by some fractional power of the number of photons in the beam — and there are many photons in the beams used by LIGO. Thus, even with the incredible sensitivity of modern gravitational-wave interferometers like LIGO, the fluctuations of spacetime are too small to be detected — unless one knows how to build a small beam interferometer of slightly improved power and phase sensitivity than what is projected for the advanced phase of LIGO![4]

For completeness, we should mention that the use of atom interferometers[9, 29] and optical interferometers[30] to look for effects of spacetime fluctuations has also been suggested. A recent proposal to build a matter-wave interferometric gravitational-wave observatory[31], using atomic beams emanating from supersonic atomic sources, sounds promising, not only for detecting gravitational radiation, but perhaps also for detecting spacetime foam.

Further Remarks

[*A Suggestion to Use Atom Interferometry Techniques.* Here we propose[9] to use laser-based atom interferometry experiments[29] in the not-too-distant future to detect spacetime fluctuations on the scales of quantum gravity at the level given by Eq. (3) and Eq. (4). In a laser-based atom interferometer, an atomic beam is split by laser beams into two coherent wave packets which are kept apart before being recombined by laser beams. The phase change of each wave packet is proportional to the proper time along its path, and so the resulting interference pattern depends on the time difference between the two paths. In the absence of spacetime fluctuations, the phase change η over a time interval τ is given by $\eta(\tau) = \Omega\tau$, where $\Omega \equiv mc^2/\hbar$ is the quantum angular frequency associated with the mass m of the atom. Due to spacetime fluctuations (Eq. (4)), there is an additonal fluctuating phase $\delta\eta$ given by

$$\delta\eta \sim \frac{(\tau t_P^2)^{1/3}}{\tau}\eta = (\tau t_P^2)^{1/3}\Omega. \tag{31}$$

For example, in 1992, Chu and Kasevich at Stanford University built an atom interferometer which used sodium atoms ($m \sim 4.5 \times 10^{-26}$ kg), and the two wave packets were kept apart for 0.2 sec.[32] For that experiment, one finds that $\eta(\tau) \sim 7 \times 10^{24}$ radians and $\delta\eta \sim 3 \times 10^{-4}$ radians. Thus one needs a precision of about 1 part in 10^{29} to look for spacetime foam (through suppression of the interference pattern), compared with the precision of 1 part in 10^{26} that

[4] This conclusion is based on the author's discussion with G. Amelino-Camelia and R. Weiss.

was then achieved. In other words, it appears that one needs a (mere) thousandfold improvement in noise sensitivity to detect spacetime fluctuations. Though the above argument, a variant of the one given by Percival[29], is necessarily short and perhaps too simplistic and overtly optimistic, hopefully the conclusion is not too far off the mark.]

5.4 Ultra-high Energy Cosmic Ray Events

The universe appears to be more transparent to the ultra-high energy cosmic rays (UHECRs)[33] than expected.[5] Theoretically one expects the UHECRs to interact with the Cosmic Microwave Background Radiation and produce pions. These interactions above the threshold energy should make observations of UHECRs with $E > 5{\cdot}10^{19}$eV (the GZK limit)[34] unlikely. Still UHECRs above the GZK limit have been observed. In this subsection, we attempt to explain the UHECR paradox by arguing[22] that energy-momentum uncertainties due to quantum gravity (significant only for high energy particles like the UHECRs), too small to be detected in low-energy regime, can affect particle kinematics so as to raise or even eliminate the energy thresholds, thereby explaining the threshold anomaly.[6] (For similar or related approaches, see Ref.[35].)

Relevant to the discussion of the UHECR events is the scattering process in which an energetic particle of energy E_1 and momentum $\mathbf{p}_1$ collides head-on with a soft photon of energy ω in the production of two energetic particles with energy E_2, E_3 and momentum $\mathbf{p}_2$, $\mathbf{p}_3$. After taking into account energy-momentum uncertainties, energy-momentum conservation demands

$$E_1 + \delta E_1 + \omega = E_2 + \delta E_2 + E_3 + \delta E_3, \tag{32}$$

and

$$p_1 + \delta p_1 - \omega = p_2 + \delta p_2 + p_3 + \delta p_3, \tag{33}$$

where δE_i and δp_i $(i = 1, 2, 3)$ are given by Eqs. (22) and (21),

$$\delta E_i = \gamma_i E_i \left(\frac{E_i}{E_P}\right)^{2/3}, \quad \delta p_i = \beta_i p_i \left(\frac{p_i}{m_P c}\right)^{2/3}, \tag{34}$$

and we have omitted $\delta\omega$, the contribution from the uncertainty of ω, because ω is small.[7]

[5] For the case of (the not-so-well-established) TeV-γ events, see Ref.[1] and references therein.

[6] Unfortunately, we have nothing useful to say about the origins of these energetic particles per se.

[7] We should mention that we have not found the proper transformations of the energy-momentum uncertainties between different reference frames. Therefore we apply the results only in the frame in which we do the observations.

Combining Eq. (34) with the modified dispersion relations[8] Eq. (23) for the incoming energetic particle ($i = 1$)and the two outgoing particles ($i = 2, 3$), and putting $c = 1$,

$$E_i^2 - p_i^2 - \epsilon_i p_i^2 \left(\frac{p_i}{E_P}\right)^{2/3} = m_i^2, \tag{35}$$

we obtain the threshold energy equation

$$E_{th} = p_0 + \tilde{\eta}\frac{1}{4\omega}\frac{E_{th}^{8/3}}{E_P^{2/3}}, \tag{36}$$

where

$$p_0 \equiv \frac{(m_2 + m_3)^2 - m_1^2}{4\omega} \tag{37}$$

is the (ordinary) threshold energy if there were no energy-momentum uncertainties, and

$$\tilde{\eta} \equiv \eta_1 - \frac{\eta_2 m_2^{5/3} + \eta_3 m_3^{5/3}}{(m_2 + m_3)^{5/3}}, \tag{38}$$

with

$$\eta_i \equiv 2\beta_i - 2\gamma_i - \epsilon_i. \tag{39}$$

Note that, in Eq. (36), the quantum gravity correction term is enhanced by the fact that ω is so small[37] (compared to p_0).

Given that all the β_i's, the γ_i's and the ϵ_i's are of order 1 and can be $\pm$, $\tilde{\eta}$ can be $\pm$ (taking on some unknown Gaussian distribution about zero), but it cannot be much bigger than 1 in magnitude. For positive $\tilde{\eta}$, E_{th} is greater than p_0. The threshold energy increases with $\tilde{\eta}$ to $\frac{3}{2}p_0$ at $\tilde{\eta} = \tilde{\eta}_{max}$, beyond which there is no (real) physical solution to Eq. (36) (i.e., E_{th} becomes complex) and we interpret this as *evading* the threshold cut.[22] The cutoff $\tilde{\eta}_{max}$ is actually very small: $\tilde{\eta}_{max} \sim 10^{-17}$. Thus, energy-momentum uncertainties due to quantum gravity, too small to be detected in low-energy regime, can (in principle) affect particle kinematics so as to raise or even eliminate energy thresholds. Can this be the solution to the UHECR threshold anomaly puzzle? On the other hand, for negative $\tilde{\eta}$, the threshold energy is less than p_0, i.e., a negative $\tilde{\eta}$ *lowers* the threshold energy.[2, 38, 39] Can this be the explanation of the opening up of the "precocious" threshold in the "knee" region? See Fig. 4. Curiously, the interpolation between the "knee" region and the GKZ limit may even explain the "ankle" region.[1]

It is far too early to call this a success. In fact there are some problems confronting this particular proposal to solve the astrophysical puzzle. The most serious problem is the question of matter (in)stability[40] because quantum

[8] The suggestion that the dispersion relation may be modified by quantum gravity first appeared in Ref.[36].

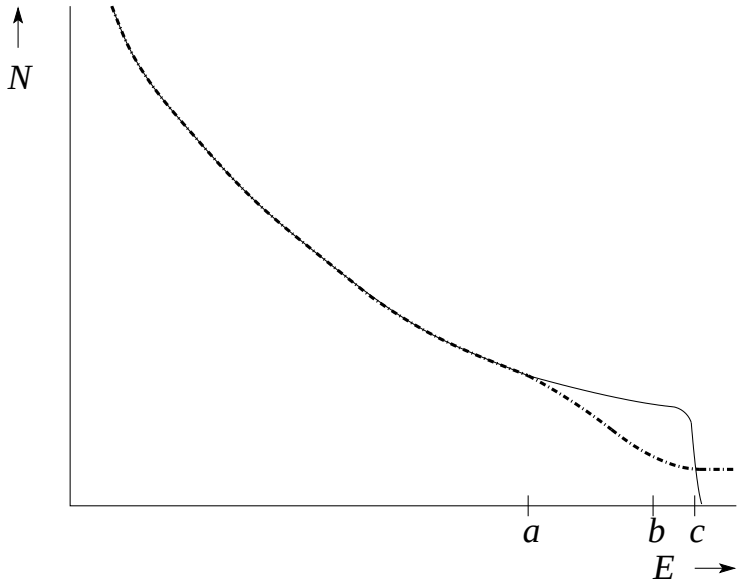

Fig. 4. Schematic plot of the number N of UHECRs versus energy E.[39] The solid curve refers to the case of ordinary threshold energy $E_{th} = p_0$. The dashed-dotted curve refers to the case of the threshold energy given by Eq. (36). The "knee" region is indicated by "a", the "ankle" region by "b", and the GZK limit by "c".

fluctuations in dispersion relations Eq. (35) can *lower* as well as raise the reaction thresholds. This problem may force us to entertain one or a combination of the following possibilities: (i) The fluctuations of the energy-momentum of a particle are not completely uncorrelated (e.g, the fluctuating coefficients β, γ, and ϵ in Eqs. (21), (22), and (23) may be related such that $\eta_i \approx 0$ in Eq. (39)); (ii) The time scale at which quantum fluctuations of energy-momentum occur is relatively short [9] (compared to the relevant interaction or decay times); (iii) Both "systematic" and "non-systematic" effects of quantum gravity are present,[2] but the "systematic" effects are large enough to overwhelm the "non-systematic" effects.

6 Summary and Conclusions

We summarize by collecting some of the salient points:

[9] Unfortunately, these two scenarios also preclude the possibility that energy-momentum uncertainties are the origin of the threshold anomaly discussed above. On the positive side, the threshold anomaly suggested by the present AGASA data may turn out to be false. Data from the Auger Project are expected to settle the issue.

- On large scales spacetime appears smooth, but on a sufficiently small scale it is bubbly and foamy (just as the ocean appears smooth at high altitudes but shows its roughness at close distances from its surface).
- Spacetime is foamy because it undergoes quantum fluctuations which give rise to uncertainties in spacetime measurements; spacetime fluctuations scale as the cube root of distances or time durations.
- Quantum foam physics is closely related to black hole physics and computation. The "strange" holographic principle, which limits how densely information can be packed in space, is a manifestation of quantum foam.
- Because the Planck length/time is so small, the uncertainties in spacetime measurements, though much greater than the Planck scale, are still very small.
- It may be difficult to detect the tiny effects of quantum foam, but it is by no means impossible.

Recall that, by analyzing a simple gedanken experiment for spacetime measurements, we arrive at the conclusion that spacetime fluctuations scale as the cube root of distances or time durations. This cube root dependence is strange, but has been shown to be consistent with the holographic principle and with semi-classical black hole physics in general. We think this result for spacetime fluctuations is as beautiful as it is strange. Hopefully it is also true!

But what is really needed is direct detection of quantum foam. Its detection will give us a glimpse of the fabric of spacetime and will help guide physicists to the correct theory of quantum gravity. The importance of direct experimental evidence cannot be over-emphasized.

We hope that the arguments given in these lectures are sufficiently compelling to encourage a determined experimental quest to detect spacetime foam, the ultimate structure of spacetime, for, as Michael Faraday, the discoverer of electromagnetic induction, once observed:

> *Nothing is too wonderful to be true, if it be consistent with the laws of nature, and in such things as these, experiment is the best test of such consistency.*

Acknowledgments

I wish to thank G. Amelino-Camelia and J. Kowalski-Glikman for inviting me to participate in this very stimulating and enjoyable Winter School. This work was supported in part by the US Department of Energy and the Bahnson Fund of the University of North Carolina. Help from A. Giugni, L. L. Ng, and T. Takahashi in the preparation of this manuscript is gratefully acknowledged. I also thank R. Weiss and especially my collaborators H. van Dam and G. Amelino-Camelia, for useful discussions. Thanks are due to B. Schumacher and M. Taqqu for conversations which led to the inclusion of the subsection on the various quantum gravity models.
